Stability of the Griffiths phase in a 2D Potts model with correlated disorder

C. Chatelain

Groupe de Physique Statistique, Département P2M, Institut Jean Lamour, CNRS (UMR 7198), Université de Lorraine, France

A Griffiths phase has recently been observed by Monte Carlo simulations in the 2D q-state Potts model with strongly correlated quenched random couplings. In particular, the magnetic susceptibility was shown to diverge algebraically with the lattice size in a broad range of temperatures. However, only relatively small lattice sizes could be considered, so one can wonder whether this Griffiths phase will not shrink and collapse into a single point, the critical point, as the lattice size is increased to much larger values. In this paper, the 2D eight-state Potts model is numerically studied for four different disorder correlations. It is shown that the Griffiths phase cannot be explained as a simple spreading of local transition temperatures caused by disorder fluctuations. As a consequence, the vanishing of the latter in the thermodynamic limit does not necessarily imply the collapse of the Griffiths phase into a single point. By contrast, the width of the Griffiths phase is controlled by the disorder strength. However, for disorder correlations decaying slower than $1/r$, no cross-over to a more usual critical behavior could be observed as this strength is tuned to weaker values.

1. Introduction

The effect of disorder on phase transitions and critical phenomena has attracted a considerable interest in the last decades. In the absence of both frustration and disorder correlation, it is now well established that a first-order phase transition is smoothed by the introduction of randomness and can be made continuous at large enough disorder strength [1]. In 2D, an infinitesimal disorder is sufficient to remove any discontinuity [2–4]. When the pure system undergoes already a continuous phase transition, the Harris criterion predicts that the universality class of the pure model will be affected by uncorrelated disorder if the specific heat diverges, i.e., if the critical exponent α is positive [5]. In this context, the q-state Potts model has been a useful toy model, because it displays a rich phase diagram involving two lines of respectively first and second-order phase transition. Along the latter, the universality class depends on the number of states q. On the practical side, efficient Monte Carlo and transfer matrix algorithms exist for this model and Conformal Invariance can be used in 2D in combination with Renormalisation Group (RG).

For comparison, correlated disorder was much less studied. Nevertheless, in some experimental situations, impurities cannot be considered as uncorrelated. This is in particular the case when they carry an electric charge or a magnetic moment and are coupled via an electromagnetic interaction. On the theoretical side, Weinrib and Halperin studied the ϕ^4 model with a random mass and showed that a new RG fixed point, distinct from the random and the pure ones, emerges in the phase diagram when the correlations of this mass decay algebraically [6]. For a sufficiently slow decay of these disorder correlations, the new fixed point becomes stable. Denoting a the exponent of the algebraic decay of disorder correlations, the perturbation is relevant when $a < d$ if the correlation length exponent ν of the pure model satisfies the inequality $\nu < 2/a$. At a new fixed point, correlated disorder is marginally irrelevant, which implies that $\nu = 2/a$ [7]. The magnetic exponent η remains small compared to $\epsilon = 4 - d$. Even though still

controversial, these predictions were confirmed by Monte Carlo simulations of the 3D Ising model with $a = 2$ [8, 9].

We recently studied the effect of correlated couplings on the 2D Potts model [10, 11] using large-scale Monte Carlo simulations. Like in the absence of disorder correlation, the first-order phase transition, occurring for a pure model when $q > 4$, was shown to be smoothed and replaced by a continuous transition. However, the new universality class was shown to be q-independent, a feature shared by the strong-disorder fixed point of the q-state Potts model with a layered McCoy-Wu-like disorder. This result is remarkably different from the continuous increase of the magnetic scaling dimension x_σ observed for the Potts model with an uncorrelated disorder. More intriguing is the fact that the phase diagram displays a Griffiths phase, as in the McCoy-Wu model, where the magnetic susceptibility diverges with the lattice size. Interestingly, such a phase has been predicted by Weinrib and Halperin, but only above the upper critical dimension $d_c = 4$. Finally, the hyperscaling relation $\gamma/\nu = d - 2\beta/\nu$ was observed to be broken in the Griffiths phase, as a result of large disorder fluctuations.

However, these observations were made for finite systems, so one cannot exclude the possibility that, at much larger lattice sizes, the Griffiths phase collapses into a single point, the critical point, where the hyperscaling relation would be restored. Moreover, the estimate of the correlation length exponent ν is incompatible with Weinrib-Halperin exact result $\nu = 2/a$, which substantiates the idea that the lattice sizes considered could be too small and that a cross-over would be observed at much larger lattice sizes. On the other hand, no significant evolution of the Griffiths phase could be observed in the range of lattice sizes studied [11]. Moreover, the conspiracy of two amplitudes that leads to the violation of the hyperscaling relation is well verified and no sign of deviation at large lattice sizes is observed.

Since larger lattice sizes are not accessible by Monte Carlo simulations, we turn our attention in this work to larger exponents a of the disorder correlations. The fact that Weinrib-Halperin predictions were confirmed by Monte Carlo simulations of the 3D Ising model with $a = 2$ could indicate that finite-size effects are weaker for larger values of a. In references [10, 11], only small values of a were considered because disorder configurations were generated by simulating an auxiliary Ashkin-Teller model on a self-dual line where its critical exponents are known exactly. The polarization density was then used to construct the couplings J_{ij} of the Potts model. Disorder correlations correspond, therefore, to the polarisation-polarisation correlations of the auxiliary Ashkin-Teller model. When moving along the self-dual line, only exponents in the range $a \in [1/4; 3/4]$ can be obtained.

In this work, we present new data for disorder correlation exponents $a = 1/3$ and $2/3$ obtained by using an auxiliary Ashkin-Teller model. In order to investigate the possible existence of a cross-over towards the Weinrib-Halperin fixed point, we also considered the values $a \simeq 1.036$ and $a = 2$ obtained using the 3D and 4D Ising models as auxiliary models to generate disorder configurations. In the first section, details regarding the models and the Monte Carlo simulations are given. In the second section, the behaviour of the magnetic susceptibility $\bar{\chi}$ is discussed. As already observed in reference [11], $\bar{\chi}$ diverge algebraically with the lattice size in a broad interval of temperatures, identified as a Griffiths phase, when a is sufficiently small. A simple explanation of this phenomenon is to assume that disorder fluctuations induce a spreading of local transition temperatures. Since these fluctuations vanish as $L^{-a/2}$, this would imply that a single peak would be recovered at large lattice sizes. Moreover, the smaller the exponent a the larger are the lattice sizes needed to observe a single peak. In the second section, numerical evidence is given that disorder fluctuations are not sufficient to explain the observed Griffiths phase, and therefore, that the latter phase cannot be expected to collapse as $L^{-a/2}$. In the third section, the possibility of a cross-over controlled by the amplitude of disorder correlations is considered. These amplitudes are compared for different disorder correlations considered and, then different disorder strengths are studied. Finally, conclusions follow.

2. Models and simulation

The classical q-state Potts model is the lattice spin model defined by the Hamiltonian [12, 13]

$$H = -J \sum_{(i,j)} \delta_{\sigma_i, \sigma_j}, \qquad \sigma_i = 0, 1, \ldots, q-1, \tag{2.1}$$

where the spin σ_i takes q possible values and is located on the i-th node of the lattice. The sum extends over all pairs (i, j) of nearest neighbours on the lattice. In what follows, the Potts model will be considered on a square lattice. As mentioned in the introduction, the phase transition is continuous for $q \leqslant 4$ and of first-order when $q > 4$. We will restrict ourselves to the case $q = 8$, i.e., a point in the regime of the first-order transition. Disorder is now introduced as bond-dependent random exchange couplings J_{ij}. The Hamiltonian becomes

$$H = -\sum_{(i,j)} J_{ij} \delta_{\sigma_i, \sigma_j}. \tag{2.2}$$

The spatial correlations between these couplings are assumed to decay algebraically with an exponent a at a large distance:

$$\overline{J_{ij} J_{kl}} - \overline{J_{ij}}\ \overline{J_{kl}} \sim |\vec{r}_i - \vec{r}_k|^{-a}. \tag{2.3}$$

For convenience, we will restrict ourselves to a binary coupling distribution, i.e., $J_{ij} = J_1$ or J_2. The presence of disorder correlations does not affect the self-duality condition of the random Potts model. Imposing J_1 and J_2 to be equiprobable and self-dual of each other, the self-dual line is given by the condition [14]

$$\left(\mathrm{e}^{\beta J_1} - 1\right)\left(\mathrm{e}^{\beta J_2} - 1\right) = q. \tag{2.4}$$

The coupling configurations are generated by independent Monte Carlo simulations of two auxiliary models: the Ising and Ashkin-Teller models. The former is defined by the Hamiltonian

$$H = -J_{\mathrm{IM}} \sum_{(i,j)} \sigma_i \sigma_j, \qquad \sigma_i = \pm 1 \tag{2.5}$$

and is equivalent to the $q = 2$ Potts model. It is well known that this model undergoes a second-order phase transition in any dimension $d > 1$. We considered hypercubic lattices of dimension $d = 3$ and $d = 4$. A few thousand spin configurations are generated at the critical point, corresponding to $\beta J_{\mathrm{IM}} \simeq 0.221655$ for $d = 3$ [15] and $\beta J_{\mathrm{IM}} \simeq 0.149694$ for $d = 4$ [16]. For each spin configuration, a two-dimensional section is cut and random couplings for the 2D Potts model are constructed as

$$J_{ij} = \frac{J_1 + J_2}{2} + \frac{J_1 - J_2}{2} \sigma_i \tag{2.6}$$

for each pair (i, j) of nearest neighbours in the 2D section. Note that, at any site i, two couplings, in two different directions, are identical. By construction, disorder correlation functions $\overline{J_{ij} J_{kl}} - \overline{J_{ij}}\ \overline{J_{kl}}$ decay as the spin-spin correlation functions of the auxiliary Ising model. Therefore, the decay is algebraic at large distances with an exponent $a = 2\beta/\nu \simeq 1.036$ for the 3D Ising model [15] and $a = 2$ for the 4D Ising model. Note that, in the second case, the exponent a is equal to the dimension $d = 2$ of the Potts model. Therefore, according to Weinrib and Halperin, disorder correlations are expected to be marginally irrelevant. As a consequence, the system falls into the same universality class as the Potts model with independent random couplings but with additional logarithmic corrections.

The second auxiliary model is the 2D Ashkin-Teller model defined by the Hamiltonian [17, 18]

$$H = -\sum_{(i,j)} \left[J_{\mathrm{AT}} \sigma_i \sigma_j + J_{\mathrm{AT}} \tau_i \tau_j + K_{\mathrm{AT}} \sigma_i \sigma_j \tau_i \tau_j \right], \qquad \sigma_i, \tau_i = \pm 1 \tag{2.7}$$

and corresponding to two Ising models coupled by their energy densities. On the square lattice, the model is self-dual along the line of the phase diagram given by $\mathrm{e}^{-2K_{\mathrm{AT}}} = \sinh 2J_{\mathrm{AT}}$. Due to the mapping onto the eight-vertex model, the critical exponents are known exactly along this line. The random couplings for the Potts model are constructed from the polarisation density as

$$J_{ij} = \frac{J_1 + J_2}{2} + \frac{J_1 - J_2}{2} \sigma_i \tau_i. \tag{2.8}$$

The disorder correlations, therefore, decay as the polarisation-polarisation correlation functions of the auxiliary Ashkin-Teller model. In this work, we considered two points on the self-dual line of the Ashkin-Teller model ($y = 0.50$ and $y = 1.25$ in the language of the eight-vertex model) corresponding to exponents $a = 1/3$ and $a = 2/3$.

The above-described spin models were simulated using Monte Carlo cluster algorithms to reduce the critical slowing-down. For the Ising and Potts models, the Swendsen-Wang algorithm was employed [19]. The Ashkin-Teller was simulated using a cluster algorithm introduced by Wiseman and Domany [20, 21].

3. Griffiths phase and disorder fluctuations

The magnetic susceptibility χ of a finite system undergoing a continuous phase transition in the thermodynamic limit is expected to display a peak whose maximum diverges with the lattice size L as $L^{\gamma/\nu}$. The location of this maximum goes towards the critical temperature T_c in the limit of an infinite system. A very different situation was observed in the 2D Potts model with a strongly correlated disorder [11]. As can be seen in figure 1, two peaks are present for $a = 1/3$ and $2/3$. The data show an algebraic increase of the average magnetic susceptibility for all temperatures between these two peaks. For this reason, this region was conjectured to be a Griffiths phase, similar to the one observed in the McCoy-Wu model. The absence of any evolution of the location of the two peaks was reported in the case $a = 0.4$. By contrast, figure 1 shows a slow evolution in the case $a = 2/3$. Since only lattice sizes up to $L = 128$ were studied, the possibility of a collapse of the Griffiths phase into a single point in the thermodynamic limit cannot be excluded. Moreover, such a collapse is even more clearly seen in figure 1 for $a \simeq 1.036$. Two peaks are still visible but they tend to come closer when the lattice size is increased. It seems natural in this case to assume that the two peaks will merge into a single one at larger lattice sizes. For disorder correlations with a faster decay $a = 2$, only one peak is observed (figure 1) and its location tends towards the critical value $\beta_c = 1$, expected from self-duality arguments.

As mentioned in the introduction, it may be assumed that the width of the Griffiths phase is due to large disorder fluctuations. It seems indeed natural to assume that the first peak is caused by the ferromagnetic ordering of large clusters with a high concentration of weak bonds J_2 while the second one corresponds to clusters of strong bonds J_1. Such large clusters are more probable when disorder correlations decay slowly. In what follows, disorder fluctuations will be compared for the different values of a considered. To be more specific, consider the general case of a lattice model with an energy density

Figure 1. (Color online) Average magnetic susceptibility of the 8-state Potts model with different disorder correlation exponents ($a = 1/3$, $2/3$, 1.036 and 2 from left to right and top to bottom) for a disorder strength $r = J_1/J_2 = 7.5$. The different curves correspond to different lattice sizes. Note that the scale of the y-axis is logarithmic.

denoted $\epsilon_{ij} = \epsilon(\sigma_i, \sigma_j)$ on the edge between the spins on sites i and j. The weak disorder limit of the partition function can be calculated using the replica trick:

$$\overline{\ln \mathscr{Z}} = \lim_{n \to 0} \frac{1}{n} \left(\overline{\mathscr{Z}^n} - 1 \right). \tag{3.1}$$

Introducing the interaction energy $\epsilon_{ij}^{\alpha} = \epsilon(\sigma_i^{\alpha}, \sigma_j^{\alpha})$ between the two spins σ_i^{α} and σ_j^{α} of the α-th replica, the partition function of n replicas reads

$$
\begin{aligned}
\overline{\mathscr{Z}^n} &= \sum_{\{\sigma_i^{\alpha}\}} \overline{\mathrm{e}^{-\beta \sum_{(i,j),\alpha} J_{ij} \epsilon_{ij}^{\alpha}}} \\
&\simeq \sum_{\{\sigma_i^{\alpha}\}} \exp \left\{ -\beta \sum_{(i,j),\alpha} \overline{J_{ij}} \epsilon_{ij}^{\alpha} + \frac{\beta^2}{2} \sum_{\substack{(i,j),(k,l), \\ \alpha,\beta}} \left(\overline{J_{ij} J_{kl}} - \overline{J_{ij}} \, \overline{J_{kl}} \right) \epsilon_{ij}^{\alpha} \epsilon_{kl}^{\beta} + \dots \right\}.
\end{aligned} \tag{3.2}
$$

The first contribution of disorder to the partition function involves the correlations $\overline{J_{ij} J_{kl}} - \overline{J_{ij}} \, \overline{J_{kl}}$, and is obviously a function of a. In order to characterise the disorder strength by a scalar, we considered the sum of these correlations, which also corresponds to the fluctuations of the couplings:

$$\Delta J_2 = \overline{\left[\frac{1}{N} \sum_{(i,j)} \left(J_{ij} - \bar{J} \right) \right]^2}^{1/2}, \tag{3.3}$$

where $N = 2L^2$ is the number of bonds of the square lattice. Since the couplings J_{ij} are constructed from the polarization density $\sigma_i \tau_i$ of the auxiliary Ashkin-Teller model (for $a = 1/3$ and $2/3$), or from the magnetization density σ_i of the auxiliary Ising model (for $a \simeq 1.036$ and 2), ΔJ_2 is related, up to a prefactor $(J_1 - J_2)/2$, to the fluctuations of the polarization, or magnetization, density. Therefore, ΔJ_2 is expected to scale as

$$\Delta J_2 \sim L^{-a/2} \tag{3.4}$$

for both auxiliary models. This result is obtained by expanding the square in equation (3.3) and integrating out the disorder correlations in the continuum limit. Up to a further factor L^d, $(\Delta J_2)^2$ is also proportional to the electric or magnetic susceptibility of the Ashkin-Teller and Ising models. The hyperscaling relation for these auxiliary models leads to $\Delta J_2 \sim L^{-\beta/\nu}$ where the exponents β/ν are equal to $a/2$ by construction of the random couplings. Equation (3.4) shows that ΔJ_2 behaves as a shift of the critical temperature $|T_c(L) - T_c(\infty)|$ in a finite system. Indeed, one expects $|T_c(L) - T_c(\infty)| \sim L^{-1/\nu}$ and, at the Weinrib-Halperin fixed point, $\nu = 2/a$.

The variance of the average coupling ΔJ_2 is plotted in figure 2 versus the lattice size in the four cases $a = 1/3$, $2/3$, 1.036 and 2. Note that in the last two cases ($a \simeq 1.036$ and $a = 2$), only the magnetization in the two-dimensional section that was used to construct the exchange couplings J_{ij} is considered. As expected, an algebraic decay with an exponent compatible with $a/2$ is observed. In figure 1, the collapse of the two peaks of the magnetic susceptibility is observed for $a \simeq 1.036$ for lattice sizes $L \sim \mathscr{O}(10^2)$ when $a \simeq 1.036$. According to figure 2, this corresponds to disorder fluctuations of the order $\Delta J_2 \simeq 0.06$. For $a = 1/3$ and $2/3$, none of the lattice sizes that were considered correspond to so small disorder fluctuations. Indeed, $\Delta J_2 = 0.159(4)$ when $a = 1/3$ for the largest lattice size $L = 128$ and $\Delta J_2 = 0.090(3)$ when $a = 2/3$. This strengthens the idea that the collapse will be observed for larger lattice sizes for $a = 1/3$ and $2/3$. Using the scaling law (3.4), one can even predict these sizes to be of the order of $L^* \simeq 128(0.06/0.16)^{-2/a} \simeq 44\,000$ for $a = 1/3$ and $L^* \simeq 128(0.06/0.09)^{-2/a} \simeq 432$ for $a = 2/3$. On the other hand, disorder fluctuations are small for $a = 2$ ($\Delta J_2 = 0.0618(4)$ already for $L = 24$), smaller than for $a \simeq 1.036$ with lattice sizes $L \sim \mathscr{O}(10^2)$.

These results do not depend on the quantity used to measure disorder fluctuations. The scaling law (3.4) suggests to use the order parameter, polarization $\overline{|\sigma_i \tau_i|}$ or magnetization $\overline{|\sigma_i|}$, of the auxiliary models as an alternative measure of the fluctuations of the couplings. This quantity will be denoted by ΔJ_1. Quantities ΔJ_1 and ΔJ_2 provide essentially the same information and, as can be seen in figure 2, take sensibly the same value, but ΔJ_1 presents the advantage of being more stable numerically. More surprising
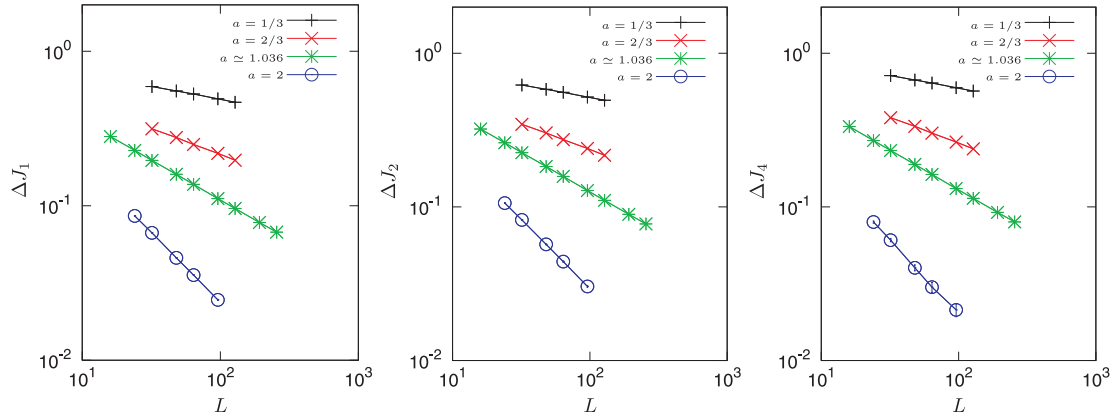

Figure 2. (Color online) Fluctuations ΔJ (up to a factor $(J_1 - J_2)/2$) of the average random couplings versus the lattice size L. Different curves correspond to different disorder correlations, i.e., to different exponents $a = 1/3, 2/3, 1.036$ and 2 (from top to bottom).

is the fact that the same conclusions can be drawn from the second contribution of disorder to the partition function (3.2). Expanding further, the next term will involve the connected four-point correlation function $\overline{J_i J_j J_k J_l}_\mathrm{c}$ of disorder. This quantity was assumed to be irrelevant by Weinrib and Halperin. We considered the fourth-order cumulant

$$\Delta J_4 = \left\{ 3 \overline{\left[\frac{1}{N} \sum_{i,j} (J_{ij} - \bar{J}) \right]^2}^{\,2} - \overline{\left[\frac{1}{N} \sum_{i,j} (J_{ij} - \bar{J}) \right]^4} \right\}^{1/4}. \tag{3.5}$$

As can be seen in figure 2, no qualitative difference between the three quantities ΔJ_1, ΔJ_2 and ΔJ_4 is observed.

However, there are small differences between the four cases $a = 1/3, 2/3, 1.036$ and a which cannot be explained only in terms of disorder fluctuations. The value of ΔJ for the largest lattice size $L = 128$ at $a = 2/3$ is close to the one estimated for $L = 48$ at $a \simeq 1.036$. Therefore, the average susceptibility should look qualitatively the same for $a = 2/3$ at $L = 128$ and for $a \simeq 1.036$ at $L = 48$. It is not clear whether this is indeed the case in figure 2. Moreover, a nice collapse of the magnetic susceptibility is observed at large β for $a = 1/3$ and $2/3$ while this is not the case for $a \simeq 1.036$ and 2. Stronger statements might be formulated by comparing thermodynamic quantities displaying universal properties. The natural candidate is the 4th-order Binder cumulant

$$U_\mathrm{M} = 1 - \frac{\overline{\langle m^4 \rangle}}{3 \overline{\langle m^2 \rangle}^2} \tag{3.6}$$

whose value at the intersection of two curves with respect to temperature is expected to be universal in the thermodynamic limit. A notable difference between different values of a is that the crossing points occur for inverse temperatures β well below $\beta_\mathrm{c} = 1$ when $a = 1/3$ and $2/3$ and very close to $\beta_\mathrm{c} = 1$ when $a \simeq 1.036$ and 2. Unfortunately, the error bars are large and do not permit to be conclusive.

Another quantity displaying universal properties is the ratio [22]

$$R_m = \frac{\overline{\langle m \rangle^2} - \overline{\langle m \rangle}^2}{\overline{\langle m \rangle}^2} \tag{3.7}$$

that measures the sample-to-sample fluctuations of magnetization. Outside a critical point, all disorder realizations are expected to lead to the same average magnetization $\langle m \rangle$ in the thermodynamic limit. Therefore, the ratio R_m vanishes as $L \to +\infty$ and magnetization is said to be self-averaging. This is no longer true at a fixed point where disorder is relevant. In this case, R_m goes towards a finite value in the thermodynamic limit. This limit is expected to be a universal quantity [23]. Numerical data for this ratio R_m are plotted in figure 3. Two distinct behaviours are observed. For $a = 1/3$ and $a = 2/3$, R_m displays a peak in the paramagnetic phase (small $\beta = 1/k_\mathrm{B} T$), followed by a broad shouldering. The latter
Figure 3. (Color online) Ratio $\overline{\langle m \rangle^2}/\overline{\langle m \rangle}^2 - 1$ of the 8-state Potts model with different disorder correlation exponents ($a = 1/3$, $2/3$, 1.036 and 2 from left to right and top to bottom) for a disorder strength $r = J_1/J_2 = 7.5$. Different curves correspond to different lattice sizes.

extends over a range of temperatures which roughly corresponds to the range between the two peaks of the average magnetic susceptibility (see figure 1). Interestingly, the estimates of R_m at any temperature in this shouldering are compatible, within error bars, for all lattice sizes $L \in [32; 128]$. Unless a sudden decay of R_m occurs at much larger lattice sizes, we are led to the conclusion that magnetization is a non-self-averaging quantity in the whole range of temperatures between the two peaks of susceptibility. This conclusion is consistent with the assumption of the existence of a Griffiths phase. On the other hand, for $a \simeq 1.036$ and $a = 2$, the peak in the paramagnetic phase is softer and is not followed by a shouldering but by a monotonous decay. More interesting is the fact that the curves corresponding to different lattice sizes cross each other at a single point, close to the self-dual point $\beta_c = 1$. This is consistent with the existence of a unique critical point at $\beta_c = 1$. Would it be possible that, in the case $a = 2/3$, the shouldering disappears at large lattice sizes to be replaced by a monotonous decay with a single crossing point for different lattice sizes? If the coupling fluctuations ΔJ provides a measure of the width of the Griffiths phase as discussed above, it should also determine the range of temperatures around β_c for which R_m is finite and size-independent. Then, the ratio R_m should look similar for $a = 2/3$ at $L = 128$ and for $a \simeq 1.036$ at $L = 48$. This is definitely not the case in figure 3. Therefore, the Griffiths phase is not solely the consequence of disorder fluctuations and there is no reason to expect the Griffiths phase to collapse into a single point as $L^{-a/2}$.

4. Griffiths phase and disorder strength

All data presented in the previous section correspond to a disorder strength $r = J_1/J_2 = 7.5$. Since the two peaks of susceptibility were interpreted as the ordering of macroscopic clusters with a majority

of strong, or weak, couplings, the disorder strength r controls the width of the Griffiths phase. One can, therefore, wonder whether disorder is not too strong in the cases $a = 1/3$ and $2/3$ which implies that a cross-over to the Weinrib-Halperin fixed point would be observed at larger lattice sizes. For the Potts model with uncorrelated disorder, strong scaling corrections depending on $r = J_1/J_2$ were indeed observed. Accurate estimates of the critical exponents became accessible only after an appropriate disorder strength was determined. The by-far most efficient technique was, in this case, to compute an effective central charge c_{eff} by transfer matrix techniques and search for the maximum of c_{eff}. The central charge is unfortunately difficult to measure by Monte Carlo simulations. Consequently, we will restrict ourselves to the observation of the effect of a variation of the disorder strength r.

Weinrib and Halperin considered disorder correlations of the form

$$C(r_{ik}) = \overline{J_{ij}J_{kl}} - \overline{J_{ij}}\,\overline{J_{kl}} = v\delta(\vec{r}_i - \vec{r}_k) + \frac{w}{|r_{ik}|^a}\,. \tag{4.1}$$

When simulating a finite system with an amplitude w much larger (or much weaker) than the value w^* taken at the fixed point, the critical behaviour may be affected by strong scaling corrections. In a simpler case of a critical system with a perturbation controlled by a parameter w, the magnetic susceptibility $\chi = -\partial^2 f/\partial h^2$ is indeed expected to scale at the critical temperature as

$$\chi(1/L, w) = L^{\gamma/\nu}\mathscr{F}\left(L^{y_w}(w - w^*)\right), \tag{4.2}$$

where y_w is the scaling dimension associated to the perturbation. The scaling function $\mathscr{F}$ involves a cross-over length $\ell \sim (w - w^*)^{-1/y_w}$. The dominant finite-size scaling behaviour $\chi \sim L^{\gamma/\nu}$ will be hidden by scaling corrections if $L \ll \ell$. Similar scaling corrections should also be expected at the long-range random fixed point, even though they are certainly more complex. In particular, Weinrib and Halperin showed that the scaling dimensions y_w can have an imaginary part, leading to oscillating scaling corrections.

In the previous section, the fluctuations of the average coupling have been compared for different exponents a. To compare now the amplitudes w of disorder correlations, note that integrating out disorder correlations leads, on the one hand, to

$$\frac{1}{N^2}\sum_{ij,kl}\left[\overline{J_{ij}J_{kl}} - \overline{J_{ij}}\,\overline{J_{kl}}\right] \simeq \frac{1}{L^2}\int_{L^2} C(\vec{r})\mathrm{d}^2\vec{r} \simeq \frac{w}{L^2}\int_0^L \frac{r\mathrm{d}r}{r^a} = w\frac{L^{-a}}{2-a} \tag{4.3}$$

while, on the other hand, the same quantity is equal to $(\Delta J_2)^2$ according to equation (3.3). The amplitude w can, therefore, be recomputed as $w \simeq (2-a)(\Delta J_2)^2 L^a$. This estimate is plotted in figure 4. Note that the

Figure 4. (Color online) Amplitude w of disorder correlations (up to a factor $(J_1 - J_2)^2/4$) versus the lattice size L. Different curves correspond to different disorder correlations, i.e., to different exponents $a = 1/3$, $2/3$ and 1.036.

amplitude w is not plotted for $a = 2$ because the definition is inappropriate in this case (the integration of the correlations involves a logarithm) and leads to $w = 0$. As can be seen in figure 4, the amplitude w does not evolve monotonously with a. This should not be a surprise because the couplings have been generated from different auxiliary models. The amplitude w for $a \simeq 1.036$ lies in between the amplitudes for $a = 1/3$ and $a = 2/3$. Therefore, the Griffiths phase and the small ν exponents reported in [11] for $a = 1/3$ and $a = 2/3$ cannot be explained as the result of strong scaling corrections. Indeed, if one assumes that the amplitude w is close to w^* in the case $a \simeq 1.036$, which would explain why the collapse of the two peaks of $\bar{\chi}$ is observed for reachable lattice sizes, one can conceive that the Griffiths phase is the result of too strong disorder correlations, i.e., $w > w^*$, in the case $a = 1/3$. However, it is hard to understand how weak correlations, i.e., $w < w^*$, would lead to a similar result for $a = 2/3$. The explanation in terms of a cross-over is, therefore, not supported by the numerical data.

However, as predicted by Weinrib and Halperin for the ϕ^4 model, the amplitude w^* at the fixed point can be a function of a. In what follows, the effect of a change of the disorder strength, and, therefore, of $w - w^*$, is studied in the case $a = 2/3$. Since $\mathscr{F}$ depends on the scaling variable $L^{y_w}(w - w^*)$, tuning the amplitude w to come closer to w^* is expected to be equivalent to increasing the lattice size L. Therefore, the cross-over, if any, should be observed when w is decreased. In figure 5, the magnetic susceptibility is plotted for two different disorder strengths $r = J_1/J_2 = 3.5$ and $r = 2$. Compared with figure 1 where the case $r = 7.5$ was plotted, it is clear that the width of the Griffiths phase is directly proportional to the disorder strength r, and, therefore, to the amplitude w. The two peaks come closer as the disorder strength is reduced. However, even for $r = 2$, the magnetic susceptibility is still very different from what is observed in figure 1 for $a \simeq 1.036$ and $r = 7.5$. One can doubt that the two curves will look similar for an even weaker disorder in the case $a = 2/3$. Very probably, the two peaks of the magnetic susceptibility

Figure 5. (Color online) On the left, average magnetic susceptibility of the 8-state Potts model with a disorder correlation exponent $a = 2/3$ and a disorder strengths $r = J_1/J_2 = 3.5$ (top) and $r = 2$ (bottom). Different curves correspond to different lattice sizes. On the right, ratio $R_m = \overline{\langle m \rangle^2} / \overline{\langle m \rangle}^2 - 1$ for the same models. Note that the horizontal scales are not the same.

for $a = 2/3$ will collapse but only when approaching $r = 1$, i.e., the pure model.

The ratio $R_m = \overline{\langle m \rangle^2}/\overline{\langle m \rangle}^2 - 1$ provides a stronger evidence that what is observed for $a \simeq 1.036$ is not what should be expected for $a = 2/3$ at a weaker disorder. As discussed when figure 1 was commented, the signature of the Griffiths phase is a size-independent ratio R_m over a finite range of temperatures. By contrast, for $a \simeq 1.036$, the ratios R_m computed at two different lattice sizes display a single crossing point at a temperature evolving towards the self-dual point $\beta_c = 1$. As observed in figure 5, the diminution of the disorder strength induces a reduction of the width of the Griffiths phase, and, as expected, of the range of temperatures where the ratio R_m appears to be size-independent. However, the ratio R_m looks surprisingly similar, up to a temperature rescaling, at different disorder strengths. Even at a disorder strength $r = 2$, the behaviour is still very different from what is observed for $a \simeq 1.036$.

5. Conclusions

New Monte Carlo simulations of the 2D 8-state Potts model with a disorder involving algebraically decaying correlations $C(r) \sim r^{-a}$ with $a = 1/3$, $2/3$, 1.036 and 2 are presented. While the analysis of the magnetic susceptibility does not permit to exclude the possibility of a collapse of the Griffiths phase into a single critical point, the study of the self-averaging ratio $R_m = \overline{\langle m \rangle^2}/\overline{\langle m \rangle}^2 - 1$ permits to be more conclusive. Two different behaviours are indeed observed for $a = 1/3$ and $2/3$ on the one hand and $a \simeq 1.036$ and 2 on the other hand. The first case is compatible with the assumption of the existence of a Griffiths phase while in the second case, the signature of a single critical point is observed. These difference cannot be explained by larger disorder fluctuations in the first case. Moreover, if the width of the Griffiths phase depends on the disorder strength for $a = 2/3$, no cross-over towards the Weinrib-Halperin critical behaviour is observed at a weak disorder. These numerical results call for a theoretical understanding of the precise mechanism behind this Griffiths phase.

Стійкість фази Гріффітса в 2D моделі Поттса зі скорельованим безладом

К. Шателєн

Група статистичної фізики, відділ P2M, Інститут Жана Лямура, CNRS (UMR 7198),
Університет Лотарингії, Франція

Використовуючи метод Монте Карло, недавно отримано фазу Гріффітса у двовимірний q-становій моделі Поттса з сильно скорельованими замороженими хаточними зв'язками. Зокрема, показано, що магнітна сприйнятливість розбігається алгебраїчно з розміром гратки в широкому інтервалі температур. Оскільки тільки відносно малі розміри граток можуть розглядатися, цікаво дізнатися, чи ця фаза Гріффітса не стягується і колапсує в одну точку, критичну точку, якщо розмір гратки стає набагато більшим. В цій статті, двовимірна восьмистанова модель Поттса вивчається чисельно для чотирьох різних кореляцій. Показано, що фазу Гріффітса не можна пояснити як просте поширення локальних температур переходу, спричинених флуктуаціями безладу. Як наслідок, зникнення останнього в термодинамічний границі не обов'язково означає колапс фази Гріффітса в одну точку. На відміну від цього, ширина фази Гріффітса контролюється силою безладу. Проте, для кореляцій безладу, що згасають повільніше ніж $1/r$, жодний кросовер до більш звичайної критичної поведінки не мав би спостерігатись, якщо ця сила зменшується до певного значення.
